CSE 142 Assignment 2, Fall 2023

3 Questions, 100 pts, due: 23:59 pm, Oct 26th, 2023

Your name: Airi Kokuryo Student ID: 2086695

Instruction

- Submit your assignments onto **Gradescope** by the due date. Upload a zip file containing:
 - (1) The saved/latest .ipynb file.
 - (2) Also save your file into a pdf version, if error appears, save an html version instead (easy to grade for written questions).
 - (3) All other materials to make your .ipynb file runnable.

For assignment related questions, please reach TA or grader through Canvas/Piazza/Email.

- This is an **individual** assignment. All help from others (from the web, books other than text, or people other than the TA or instructor) must be clearly acknowledged.
- Most coding parts can be finished with only 1-2 lines of codes.
- Make sure you have installed required packages: scikit-learn.
- Double click to edit each markdown cell.

Objective

- **Task 1:** Maximum likelihood estimation (math)
- **Task 2:** Linear Regression (with Scikit-learn)
- **Task 3:** Principle Component Analysis (with Scikit-learn)

Question 1 (Maximum likelihood estimation and Posterior, 20 pts)

Assume we have a coin that has some unknown probability h of coming up heads (and probability 1-h of coming up tails). If the coin is flipped five times getting three heads and two tails (**HHHTT**) then:

(a -- 10pts) What is the maximum likelihood estimate for h?

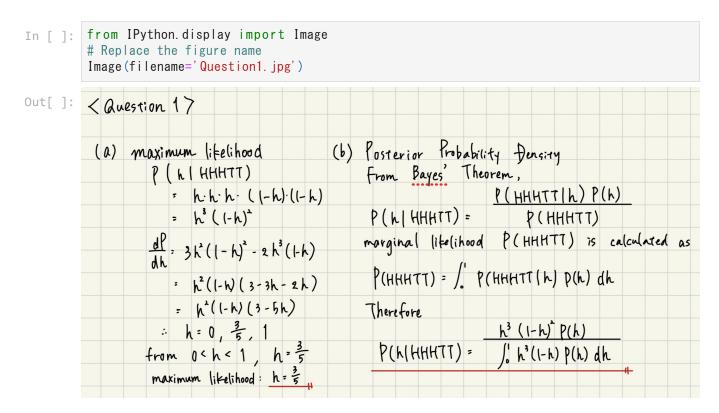

(b -- 10pts) Assume that (before flipping the coin) we have a prior density p(h) for the various values of $h \in [0, 1]$. Give the formula for the posterior probability density $p(h \mid \mathbf{HHHTT})$ as a function of the prior p(h).

For Question 1(b), the solution is acceptable if the formula contains an integral.

Solution (a):

Solution (b):

If you are not familair with Latex, you may attach a figure/screen-shoot and display the code below.

Question 2 (Linear Regression, 40 pts)

In this question, you will be using **Scikit-learn** to empirically apply the Linear Regression model. We will adopt an advertisement dataset **Advertising.csv** from Kaggle.

Reading data using Pandas

```
In []: # Read the dataset you will be working on
# The dataframe loaded with pandas is named as data
import pandas as pd
data = pd. read_csv('Advertising.csv', index_col=0) # Modify your data path accordingly
# Take a look at the first 5 rows
data. head()
```

```
Out[]:
               TV Radio
                           Newspaper Sales
          1 230.1
                     37.8
                                  69.2
                                        22.1
             44.5
                     39.3
                                  45.1
                                        10.4
            17.2
                     45.9
                                 69.3
                                         9.3
          4 151.5
                     41.3
                                  58.5
          5 180.8
                     10.8
                                  58.4
                                        12.9
```

```
In [ ]: data shape

```

Features and responses

What are the features?

- **TV:** advertising dollars spent on TV for a single product in a given market (in thousands of dollars)
- Radio: advertising dollars spent on Radio
- Newspaper: advertising dollars spent on Newspaper

What is the response?

• **Sales:** sales of a single product in a given market (in thousands of items)

What else do we know?

- There are 200 **observations**, and each observation (each row) is a single market.
- **Your main task**: predict the sales of a single product in a given market.
- Since the response variable is continuous, this is a **regression** problem.

Linear regression

Pros: fast, no tuning required, highly interpretable

Cons: adopting the linear regression is unlikely to always generate the best predictive accuracy, since Linear Regression presumes a linear relationship between the features and response. This assumption may not always make sense. (But if one can *transform* the features so that do have a linear relationship, sometimes progress can be made, for example by taking logs.)

Expression:

- y: the response
- β_0 : the intercept
- β_1 : the coefficient for x_1 (the first feature)
- eta_i is the coefficient for x_i (the ith feature, $i \in \{1,2,\ldots,n\}$)

For this regression task:

```
Sales = \beta_0 + \beta_1 \times TV + \beta_2 \times Radio + \beta_3 \times Newspaper
```

The β values ($\beta = [\beta_0, \beta_1, \beta_2, \beta_3]$) are called the **model coefficients**. These values are "learned" during the model fitting step using the "least squares" criterion. Then, we can make use of the fitted model to make predictions!

Prepare the dataset for training use

- Scikit-learn expects X (feature matrix) and y (response vector) to be NumPy arrays.
- Pandas is built on top of NumPy, and exposes numpy methods. Thus, X can be a pandas DataFrame, y can be a pandas Series!

```
In []: # Prepare the feature X
X = data[['TV', 'Radio', 'Newspaper']]

# check the type and shape of X
print(type(X))
print(X. shape)

<class 'pandas. core. frame. DataFrame'>
(200, 3)

In []: # Prepare the response Y
y = data['Sales']
# check the type and shape of y
print(type(y))
print(y, shape)

<class 'pandas. core. series. Series'>
(200.)
```

Question 2.1 (Split the dataset into train and test parts, 5 pts)

For features X and response y, use **sklearn** to perform the the splitting of dataset: 80% for train data, 20% for the test data.

Double check the shape of train and test data:

```
In []: # default split is 80% for training and 20% for testing print(X_train. shape) print(y_train. shape) print(X_test. shape) print(y_test. shape)

(160, 3) (160,) (40, 3) (40,)
```

Question 2.2 (Train a Linear regression model via Scikit-learn, 10 pts)

Assume you model is named as **model**, and you train the linear regression model to fit on the training data.

```
# Name your linear regression model as 'model', so proceeding cells won't run into error
       from sklearn.linear_model import LinearRegression
       model = LinearRegression(). fit(X_train, y_train)
       In [ ]: # Take a look at your model coefficients
       import numpy as np
       print(np. round(model. intercept_, 4))
       print([np. round(val, 4) for val in model.coef_])
       2.8584
       [0.0464, 0.1832, 0.0019]
In [ ]: # Match the feature names with the trained coefficients
       list(zip(data.columns[:3].tolist(), model.coef_))
Out[]: [(',TV', 0.04641350385297018),
        ('Radio', 0.1832215828623365),
        ('Newspaper', 0.0019077706874898734)]
```

Question 2.3 (Interpreting model coefficients, 10 pts)

The coefficients of each feature are printed above.

Your tasks:

- What is the trained linear regression model?
- (replace β_i below with the trained coefficients, reserve four decimal places, 5 pts)

```
Sales = 2.9423 + 0.0459 \times TV + 0.1824 \times Radio + 0.0012 \times Newspaper
```

• **(Open) question (5 pts)**: how do you interpret the coefficient of **TV** (β_1)?

From the coefficient being positive, it could be interpret that this would contribute to the sales. Also, it will contribute more than Newspaper, which has very small effect on the sales, but less tha Radio.

Making predictions

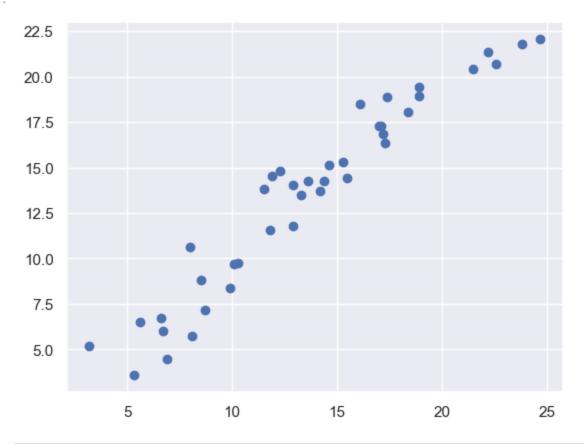

```
In [ ]: # make predictions on the testing set
y_pred = model.predict(X_test)
# Print the test accuracy score from your trained linear regression model
model.score(X_test, y_test)
```

Out[]: 0.929152852466682

Trained linear regression model:

```
In [ ]: import matplotlib.pyplot as plt
plt. scatter(y_test, y_pred)
```

Out[]: <matplotlib.collections.PathCollection at 0x20c1d07b1d0>

```
In [ ]: Sales = 2.9389 + 0.0458 * data['TV'] + 0.1885 * data['Radio'] + (-0.001) * data['Newspaper int(Sales)
```

```
1

```

Model evaluation metrics for regression

Evaluation metrics for classification problems, such as **accuracy**, are not useful for regression problems. Instead, we need evaluation metrics designed for comparing continuous values. (Since predictions would hardly ever exactly match the measured quantities.)

Mean Squared Error (MSE) is the mean of the squared errors:

$$\frac{1}{n}\sum_{i=1}^n(y_i-\hat{y}_i)^2$$

Root Mean Squared Error (RMSE) is a popular evaluation metric for regression, which is defined as the square root of the mean of the squared errors:

$$\sqrt{\frac{1}{n}\sum_{i=1}^n(y_i-\hat{y}_i)^2}$$

Question 2.4 (Evaluate your predictions on test features with RMSE metric, 5 pts)

Hint: you may calculate MSE using scikit-learn, but RMSE is a little bit different from MSE.

RMSE=1. 42579631646171

Question 2.5 (Does the feature 'Newspaper' help? 10 pts)

Does the feature **Newspaper** contribute or impair the model prediction? Now repeat previous procedure:

- For features X, only select **TV** and **Radio**; response y is unchanged.
- Split the dataset as what you have done before.
- Fit/Train the model on the train data.
- Make predictions on the test data.
- Compute the RMSE of the predictions on the test data.
- Show your observations!

Reminder: if you use random_state while splitting the dataset, make sure the value of random_state is the same for the two splits. So that the test data only differs in the column of **Newspaper**.

rmse=1.771425417303351

Your observations:

Question 3 (PCA, 40 pts)

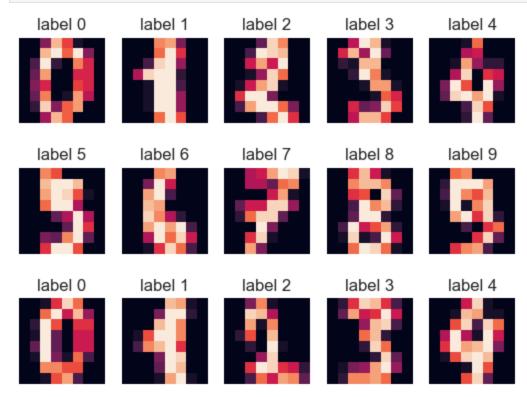

In this question, we will explore how PCA helps with reducing the dimensionality through scikit-learn. We will adopt a simple digits dataset contained in scikit-learn.

```
In []: # import libraries
%matplotlib inline
import matplotlib.pyplot as plt
import seaborn as sns;
sns. set()

In []: from sklearn.datasets import load_digits
data_digit = load_digits()
data_digit.data.shape

Out[]: (1797, 64)
```

As you have seen above, there are 1797 rows and 64 columns in this dataset. Each row denotes the pixel values of an image. Since each image is 8*8 (in pixel), the dimension of each feature is 64. Let's take a look at a few images contained in this dataset.

PCA finds uncorrelated orthogonal axes (principal components) in a high dimensional space (i.e., 64) to project the feature onto principal components.

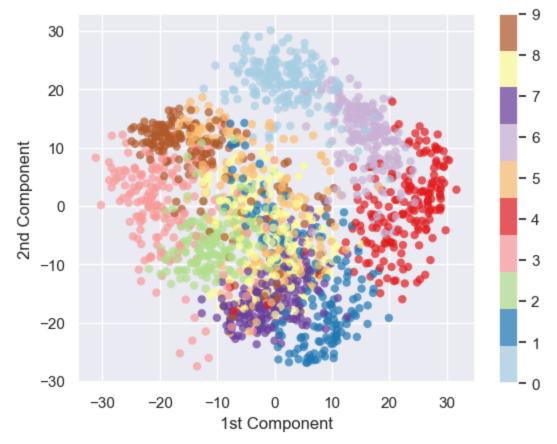

Question 3.1 (PCA and dimensionality deduction with Scikit-learn, 10 pts)

In this question, you may use the implementation of PCA from scikit-learn, as imported below. Detailed explanations of parameters settings are available in this link.

Your task in this question:

Fit the model with feature X (**data_digit.data** for this dataset) and apply the dimensionality reduction on X, keep 2 components.

With the reduced dimension of features, we can now visualize the projected/reduced features in a 2-dimension plot as below. There are hardly any overlaps between digit 0 and any other digits. While in the central area of the figure, features are not well separable.

<Figure size 1800x800 with 0 Axes>

Question 3.2 (How many components do we need? 15 pts)

In practice, suppose you are given a high-dimension dataset, and you are interested in performing a dimension reduciton with PCA. How many conponents do we need? One method is to look at the distribution of the explained variance ratio w.r.t. each component.

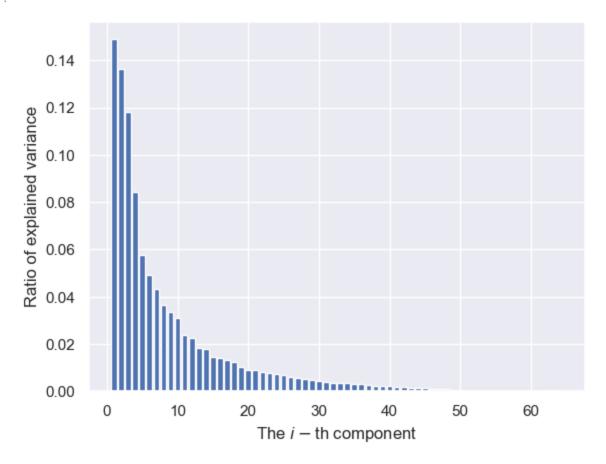

In this question, you may use the function explained_variance_ratio in **pca** (with scikit-learn) to address this question. Detailed explanations of parameters settings are available in this link.

Your task in this question:

Print the ratio of variance explained by each of the selected components;

Visualize with matplotlib or seaborn (x axis: i-th component; y axis: the corresponding ratio of explained variance).

Out[]: Text(0, 0.5, 'Ratio of explained variance')

How to obtain eigen values and vectors from sklearn PCA

- Eigen values -- your-PCA-model\.explained_variance_
- Eigen vectors -- your-PCA-model.components_

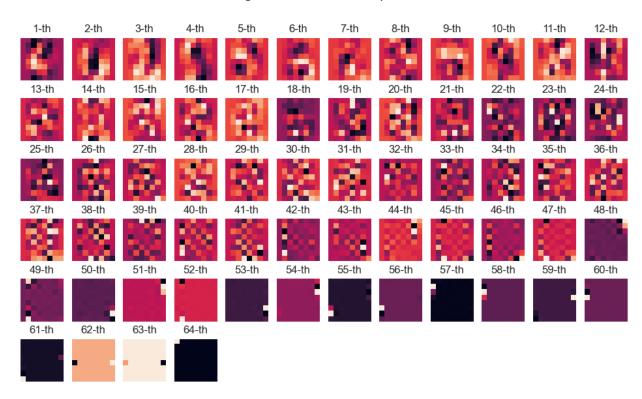

Eigen vectors (Eigen digits)

```
# Default # of components is the dimension of feature space
In [ ]:
         pca = PCA()
         pca. fit (data_digit. data)
         h = 6
         w = 12
         fig, axes = plt.subplots(h, w)
         fig. set_size_inches(12, 7)
         for i in range(h):
             for j in range(w):
                 idx = i * w + j
                 if idx > 63:
                     axes[i, j].axis('off')
                 else:
                     axes[i, j]. imshow(pca. components_[idx]. reshape(8, 8))
                     axes[i, j].axis('off')
```

```
axes[i, j].set_title(f' {idx + 1}-th')
fig.suptitle('The eigen vector of each component')
```

Out[]: Text(0.5, 0.98, 'The eigen vector of each component')

The eigen vector of each component

Question 3.3 What are your observations from the visualized eigen vectors? (5 pts)

MY ANSWER HERE

Your solutions for Question 3.3:

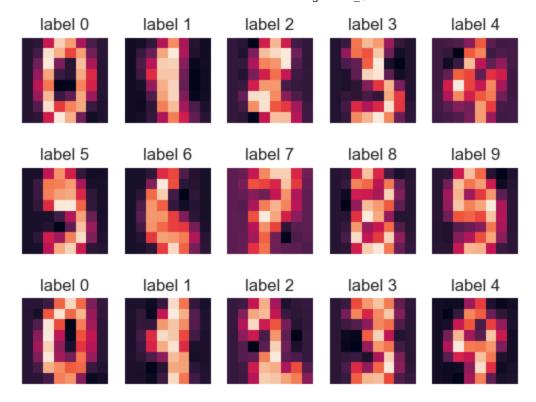

Feature reconstruction:

Suppose you only want to preserve 80% variance after applying PCA for the dimension reduction, due to storage issues, etc.

```
In []: # Use pca from sklearn to fit on the feature space
    pca_08 = PCA(0.8). fit(data_digit. data)

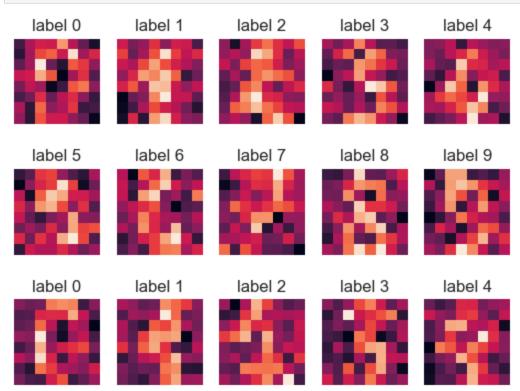

# Reconstruct
    lower_dimension = pca_08. fit_transform(data_digit. data)
    reconstructed = pca_08. inverse_transform(lower_dimension)

# Display the reconstructed images (with a much lower dimension)
    display_digits(reconstructed)
```

Assume now you are given only a set of perturbed images (with some random noise). As shown below, the figures become much more difficult to recognize.

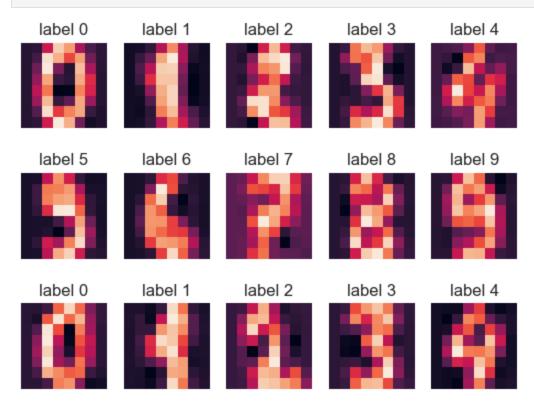

In []: # Apply random noise on clean images
 noisy_imgs = np. random. normal(data_digit. data, 5)
 # Display the noisy images
 display_digits(noisy_imgs)

Question 3.4 Does PCA mitigate the random noise? (10 pts)

Your tasks:

- Perform feature reconstruction on $noisy_imgs$ (preserving 80% variance after applying PCA for the dimension reduction)
- Explain your understandings on why PCA reconstructs cleaner images.

Your written answers for Question 3.4:

Since PCA reduces dimension, only the most important concept will remain and other noises will be either condensed or erased. Specifically, PCA reduces the dimensionality of high-dimensional datasets, while noise has a high frequency and is reduced by PCA.
